Clinico-Demographic Profile and Pregnancy Outcome in Placenta Previa: A Study from Tertiary Care Hospital

Haque H1 Pandit U2

ABSTRACT

Introduction: Placenta previa is an obstetric complication which causes considerable maternal and fetal morbidity and mortality during pregnancy. This study is done with the objective to find out the clinico-demographic factors associated with placenta previa and to analyze maternal and perinatal outcome in these cases. Methods: This was a retrospective study done in the department of Obstetrics and Gynecology of Nepalgunj Medical College Teaching Hospital, Nepalgunj, a tertiary care hospital from Midwestern Nepal. Relevant data were retrieved from maternity register from June 2015 to May 2017. All women who had undergone caesarean section for placenta previa were included in this study. Result: Out of total 5812 deliveries during the study period there were 50 caesarian sections done for placenta previa which is 0.86% of total deliveries. Maximum number of mothers belonged to 26-30 years of age group. Commonest type of placenta previa was minor type. About 72% were multiparous. 20% had previous LSCS and 24% had previous abortion. Postpartum hemorrhage was present in 36% mothers and 32% received blood transfusion. About 64% new born were preterm and low birth weight. 34% babies had less than 7 apgar score at 5 min. Still births were 6%. Conclusion: Placenta previa poses greater risk and need of blood transfusion to mother as well as birth of preterm and low birth weight babies which leads to perinatal morbidity and mortality. Timely diagnosis, regular antenatal check up and effective management may improve pregnancy outcome.

Key words: Profile, pregnancy outcome, placenta previa, Nepalgunj medical college

INTRODUCTION

Placenta previa is an obstetric complication which causes considerable maternal and fetal morbidity and mortality during pregnancy1. When the placenta is inserted wholly or partially in the lower uterine segment it is termed as placenta previa. The incidence is approximately 4-5 per 1000 pregnancies2,3. About one-third cases of antepartum hemorrhage belong to placenta previa. For clinical purpose, placenta previa is graded into major and minor types. If the placenta lies over the cervical os it is considered as a major previa, else it is a minor previa2. Advancing maternal age, multiparity, previous Cesarean delivery, abortion and male fetuses all conferred increased risk for placenta previa3. Pregnancies complicated with placenta previa had significantly higher rates of second-trimester bleeding, pathological presentations, abruptio placentae, congenital malformations, perinatal mortality, Cesarean delivery, Apgar scores at 5 min lower than 7, postpartum hemorrhage, postpartum anemia and increased hospital stay as compared to pregnancies without placenta previa6. Present study was to find out the clinico-demographic factors associated with placenta previa and to determine maternal and perinatal outcome.

MATERIAL AND METHODS

This is a retrospective study done in the department of Obstetrics and Gynecology, Nepalgunj Medical College Teaching Hospital, Nepalgunj, a tertiary care hospital from Midwestern Nepal. Relevant data were collected from maternity register for the period of two years from June 2015 to May 2017. Approval for the study was taken from department. Study population was 50 mothers. All women who had undergone caesarean section for placenta previa were included in this study. Relevant clinico-demographic data were collected and maternal and neonatal outcome were observed, tabulated, analysed and presented in percentage.

RESULT

During the two year period there were 5812 deliveries, out of them 1692 were undergone caesarean section. Among them, caesarean section done for placenta previa was 50, which is 0.86 percent of total deliveries. Table I shows 16 (32%) belonged to 26-30 years of age group followed by 15 (30%) to 21-25 years age group and 12 (24%) to 31-35 years of age group. Four (8%) women were more than 35 years of age.

Placenta previa is an obstetric complication which causes considerable maternal and fetal morbidity and mortality. This study is done with the objective to find out the clinico-demographic factors associated with placenta previa during pregnancy. This is a retrospective study done in the department of Obstetrics and Gynecology, Nepalgunj Medical College Teaching Hospital, Nepalgunj, a tertiary care hospital from June 2015 to May 2017. Approval for the study was taken from the ethical committee of Nepalgunj Medical College Teaching Hospital. Relevant data were retrieved from maternity register from June 2015 to May 2017. All women who had undergone caesarian section for placenta previa were included in this study. Relevant clinico-demographic data were retrieved from the same. Study population was 50 mothers. Obstetric complications (postpartum hemorrhage, blood transfusion), neonatal outcome, baby weight and sex of the baby were noted. Placenta previa is graded into major and minor types. If the placenta is inserted wholly or partially in the lower uterine segment it is termed as placenta previa. The incidence is approximately 4-5 per 1000 deliveries. In a study done in Nepalgunj medical college hospital, 0.86% of total deliveries were placenta previa which is 0.55% of cesarean sections were done for placenta previa. This finding could be due to the reason that Nepalgunj medical college hospital is a major tertiary referral centre in mid western and far western region. High risk cases are usually referred from various district hospitals of the region. In the meta analysis reviewing studies on placenta previa between 1950-1996, among 13,992 patients diagnosed with placenta previa, the reported incidence of placenta previa ranged from 0.28%- 2.0%. This is similar with our observation. In this study, almost 1/3rd of subjects were more than 30 years of age and similar number belonged to 26- 30 years age group. This finding is also similar to same study.

Study reveals that placenta previa was more common in multiparous women i.e. in 72% of cases. Various studies have shown that multi parity is an important risk factor for placenta previa. Similar finding was reported in the study done by Lama S. et.al. Findings suggest that 22% of participants were undergone previous LSCS and 24% had history of previous abortion. Study done by Ananth CV et al. shows a strong association between a previous cesarean delivery, spontaneous or induced abortion, and the subsequent development of placenta previa. In a different study done by A.S Anzaku et.al. in 135 cases of placenta praevia among 10,895 deliveries found previous history of caesarean section in 40.7% and previous history of abortion in 20.4%.

Table IV shows neonatal outcome. About 32(64%) babies were preterm and same numbers of babies were low birth weight. In 17(34%) babies, apgar score in 5 minute was less than 7. The still birth deliveries were 3(6%). Male baby outnumbered female baby, 29(58%) of all deliveries.

**DISCUSSION**

Placenta previa invites serious complications during pregnancy which is associated with increased maternal and perinatal morbidity and mortality.

In this study out of total 5812 deliveries, 0.86% cases were undergone caesarian section for placenta previa. This finding is slightly higher than the result obtained by Ojha N. who did similar study at TUTH, Kathmandu and found that 0.55% of cesarean sections were done for placenta previa. This finding could be due to the reason that Nepalgunj medical college hospital is a major tertiary referral centre in mid western and far western region. High risk cases are usually referred from various district hospitals of the region. In the meta analysis reviewing studies on placenta previa between 1950-1996, among 13,992 patients diagnosed with placenta previa, the reported incidence of placenta previa ranged from 0.28%- 2.0%. This is similar with our observation. In this study, almost 1/3rd of subjects were more than 30 years of age and similar number belonged to 26- 30 years age group. This finding is also similar to same study.

Study reveals that placenta previa was more common in multiparous women i.e. in 72% of cases. Various studies have shown that multi parity is an important risk factor for placenta previa. Similar finding was reported in the study done by Lama S. et.al. Findings suggest that 22% of participants were undergone previous LSCS and 24% had history of previous abortion. Study done by Ananth CV et al. shows a strong association between a previous cesarean delivery, spontaneous or induced abortion, and the subsequent development of placenta previa. In a different study done by A.S Anzaku et.al. in 135 cases of placenta praevia among 10,895 deliveries found previous history of caesarean section in 40.7% and previous history of abortion in 20.4%.
This study indicates 18 (36%) cases of placenta previa were complicated by postpartum hemorrhage and 16 (32%) women were given blood transfusion. Similar result was observed in the study done by Ojha N. In a A Systematic Review and Meta-Analysis by Dazhi Fan et al, who draw result from 1148 studies, 11 included in the meta-analysis, which involved 5146 unique pregnant women with placenta previa found that overall pooled incidence of PPH was 22.3% 13.

Regarding neonatal outcome, Infants born to women with placenta previa had significant number of low birth weight, prematurity, Apgar scores of <7 at 5 min. and stillbirth. This observation is consistent with previous studies 14,15. The possible explanation for these could be that the bleeding associated with placenta previa may lead to hypoxia, intrauterine growth restriction, and prematurity with underdeveloped organ systems. There was slight preponderance of male babies in our study. This finding is consistent with the study done by Wen SW et al 16.

CONCLUSION
Placenta previa is one of the main indications for caesarian sections. Grand multiparty mother has got more risk to have abnormal placentation. Placenta previa also commonly invites complications like post partum hemorrhage followed by blood transfusion. So that early detection of placentation by ultrasound and timeliness intervention prevents the maternal and perinatal morbidity and mortality.
