Doxorubicin Deteriorates the Histomorphology of the Kidneys of Albino Rats

Pandeya A¹, Jha CB², Karki S³, Rauniar GP¹

ABSTRACT

Background and Objectives: Nephrotoxicity is one of the limiting factors for using doxorubicin as an anticancer chemotherapeutic. Reactive oxygen species and cytokines have been implicated in the nephrotoxicity induced by doxorubicin. The main objective of the present study is to identify and compare the histomorphological features in kidneys of albino rats and gross morphological features such as weight of rats and weight of the kidneys due to administration of doxorubicin. Materials and Methods: In the study, albino rats were taken as the animal model. Sixty animals were taken as the sample size. They were divided into two equal groups: experimental (n=30) and control (n=30). Rats of experimental group were treated with anticancer drug doxorubicin at a single intraperitoneal dose of 10 mg/kg body weight while the Control group of rats received a similar volume of 0.9% normal saline. The ethical clearance was taken prior to the research from IERB committee BPKIHS Dharan. Results: Our results showed that there was high effect of drug in experimental groups of rats. It was seen that there was significant decrease in the body weight and weight of kidneys. The final body weight and kidney weight between experimental and control group showed the significant difference. Similarly there were no significant differences in the normal architecture between the male and female rats. The normal renal histological features were seen on the kidneys in the control group whereas the rats intervened with the drug had some disrupted histological features which reveal the toxicity of the drugs in the kidneys. Conclusion: The study showed toxicity of the drug in the kidneys of experimental groups of rats irrespective of gender and suggest that doxorubicin causes significant loss of the body weight and weight of kidneys and causes the disruption in the normal histological features.

Keywords: Doxorubicin, nephrotoxicity, rats

INTRODUCTION

Doxorubicin, an anthracycline isolated from Streptomyces peucetius, has potent antitumor activity against a wide range of human malignancies. The optimal use of doxorubicin is limited by a number of side effects; the most important are cardiotoxicity, haematotoxicity and a dose limiting nephrotoxicity. Doxorubicin has been used for more than 30 years for the treatment of various malignancies, including tumors in breast tissue, bile duct, endometrial tissue, esophagus and liver as well as osteosarcomas, soft tissue sarcomas, and non-Hodgkin's lymphoma. It acts by inhibiting the enzyme topoisomerase II, which leads to double strand breakage in the DNA double helix and also by intercalating with the DNA. The exact mechanism and chance of doxorubicin induced obvious nephrotoxicity is not yet specifically known. However, it has been suggested by many investigators that cellular damage induced by doxorubicin is mediated by the formation of an iron anthracycline free radical. Cardiac and renal damage has also been reported in laboratory animals following treatment with doxorubicin. Nephropathy has also been reported in cancer patients on doxorubicin therapy, as well as in experimental animals treated with doxorubicin. However, it is not yet clear what duration of doxorubicin therapy induces nephrotoxicity. Doxorubicin induced changes in the kidneys of rats include increased glomerular capillary permeability and tubular atrophy. Nitric oxide is a free radical gas which acts both as a cytoprotective and cytotoxic agent. Nitric oxide is generated by either endothelial nitric oxide synthase or inducible nitric oxide synthase. Possible role of doxorubicin in nitric oxide synthase metabolism occurs via direct or indirect stimulation of nitric oxide production, and this might be a consequence of increased free radical generation. Free radical production and/or nitric oxide release induced by doxorubicin has been found to be responsible for the doxorubicin-induced toxicity. The most frequently investigated effect of Doxorubicin on a molecular level is its tendency to generate a large amount of reactive oxygen species through the formation of semiquinone-type free radicals.

Since kidneys are the important organs for the survival of living beings and anticancer drugs have much more effect on kidneys. Therefore the present study has been designed to identify the histomorphological changes in kidneys of albino rats due to administration of doxorubicin in comparision to control groups.

METHOD AND MATERIALS

Animals

Sixty healthy Wistar Albino rats weighing 150-200gm were obtained from the animal house of BPKIHS, Dharan. They were housed in well ventilated room at controlled ambient
temperature (25±5°C) with a 12 hours alternating light and dark cycle. Animals were kept in groups consisting of less than five rats per cage made up of propylene (size=40cm×25cm×15cm) with husk bed. The cages were cleaned and husks were changed at regular intervals. The water bottles were also regularly cleaned to inhibit any fungal growth. The ethical clearance was taken prior to the research from Institutional Ethical Review Board (IERB) Committee, BPKIH Dharan.

Diet Regimen
All rats were fed standard pellet diet and Bengal gram. They were given tap water and libitum. All the experimental works were carried out as per the ethical guidelines of Nepal Health Research Council (NHRC) for the care and use of animals in health research in Nepal.

Animal Groups and Treatment Regimen
Rats were randomly divided into three groups:

- Group A - Long term (16th week)
- Group B - Mid-term (8th week)
- Group C - Short term (2nd week)

The short term group was again divided into two sub-groups

Then the chest was opened and the right atrium was nicked by a scissor or knife (scalpel) to permit the drainage of blood. Thereafter, the physiological saline was perfused to flush out the blood. The fixative bouin’s fluid was then transfused with the help of three ways stopcock. Approximately 200 ml of each fluid was perfused. Perfusion was stopped when clear fixative drops started oozing out from the snout of the animal. After completion of perfusion, the kidneys were isolated with the help of scalpel and forceps and weight was measured and post fixed for 24 hours by the same fixative. After 18 hour fixation in bouin’s fluid, the tissue was processed and histological slides were prepared from vertical sections from the polar and the equatorial regions of each kidney. Micrometer was used for quantitative measurement of parameter; diameter of renal corpuscles and glomerulus were observed qualitatively in histological slides. Diameter (D) of each renal corpuscles and glomerulus was measured.

Quantitative Measurement
Ocular and stage micrometers were used for quantitative measurements of different parameters like diameter of renal corpuscles, glomerulus.

Statistical Analysis
After completion of the experiment, data was entered in the microsoft excel software program. Statistical analysis was performed using the Statistical Package for Social Sciences (SPSS) 16 version. Depending upon the nature of the data collected, statistical tool independent-sample t-test and paired sample t-test were used to determine the significance of histomorphological changes, body and kidney weight and size of cells between experimental and controls. Statistical significance was set at 5% level of significance.

RESULTS
In this study, 60 wistar albino rats were taken. They were divided into 2 groups, control and experimental. Control and experimental groups both were again divided into 3 sub-groups each having equal number of male and female rats. The different data of the result showed that there was high effect of the drug in short term, mid-term and long term groups of rats.
It was observed that mean difference between the initial and the final weight of rats in experimental and control groups was highly significant ($P<0.001$) in short term, mid-term and long term groups of rats. The mean difference of the weight of right and left kidney in experimental and control groups was not statistically significant ($P>0.05$) in both short term and long term group of rats whereas the mean difference of the weight of right and left kidney in experimental and control groups of rats was highly significant ($P<0.001$) in mid-term group of rats.

In this study we observed that the mean difference between the diameter of renal corpuscles in experimental and control group was not statistically significant ($P>0.05$) in both short term and long term group of rats whereas the mean difference between the diameter of renal corpuscles of experimental and control group was statistically significant ($P<0.05$) in mid-term group of rats. And in case of glomerulus the mean difference between the diameter in experimental and control group was statistically significant ($P<0.05$) in both short term and long term group of rats whereas the mean difference between the diameter of glomerulus of experimental and control group was not statistically significant ($P>0.05$) in mid-term group of rats (Table I).

Figure 1: A, B, C and D show the diameter of renal corpuscles and glomerulus of control (all control groups), short term experimental group, mid-term experimental group and long term experimental group respectively.

Table I: Changes in morphometric parameters in albino rats
DISCUSSION

Anticancer therapy usually demolishes the physiological homeostasis and affects multiple organs during treatment process. Effective anticancer therapy with anthracycline is limited because of its toxicity to various organs including kidneys\textsuperscript{11}. The toxicity has been attributed to radical formation and oxidant injury. Nephrotxic action of doxorubicin is also considered to be via drug induced free radical generation. The formation of free radical as well as an increase in response to doxorubicin treatment has already been documented. The disturbance in oxidant-antioxidant systems results in tissue injury that is demonstrated with protein oxidation in tissues and protein oxidation in renal tissue is recognized as one of the possible biochemical mechanisms of doxorubicin induced nephrotoxicity\textsuperscript{11}.

The study was designed with the rationale to find out the effect of the doxorubicin in the kidneys. In this study, albino rats were taken as the animal model. 60 rats were taken as the sample size. The rats of long term group of both control and experimental were sacrificed together after 16th week of intervention. Similarly the rats of mid-term and the short term group of both control and experimental were sacrificed together after 8\textsuperscript{th} week and 2\textsuperscript{nd} week of intervention respectively. The experimental groups were given single dose of 10mg/kg body weight of doxorubicin intraperitoneally and control groups were given normal saline of equal volume of the drug. The kidney section of control group showed normal histological feature of the kidney similar to those observed by other researcher. The reduction in animal body weight in experimental group may be attributed to the cytotoxic effect of doxorubicin since it cause myelosupression, anemia, loss of appetite and poor feeding, or it may inhibit protein synthesis.

In the present study the experimental group of rats demonstrated the general weakness, loss of appetite and reduction in body weight. The weight loss might be due to the loss of appetite causing mobilization and utilization of fat and change in metabolic rates. However, the final weight of rats of control groups demonstrated increase in body weight. This result is similar from the study conducted by Boonsanit D et al. which shows that doxorubicin affects the growth of rats with significant reduction in daily food intake and body weight\textsuperscript{11}.

The results in the present study showed the increase in diameter of renal corpuscles and glomerulus in the doxorubicin injected rats as compared to control group of rats. Similar result was observed in the study done by Rashid S et al. which showed that normal renal architecture was observed in control group whereas renal lesions, inflammation, glomerular congestion and interstitial hemorrhage were observed in doxorubicin treated groups\textsuperscript{11}.

CONCLUSION

In summary, present study demonstrated decreased in the body weight and weight of kidneys in all experimental groups of rats as well as deteriorative effect of doxorubicin was observed on both glomerulus and renal corpuscles of albino rats. The histomorphological adverse changes occurs in kidneys of all the experimental groups of rats without gender variation due to administration of doxorubicin.
