Frailty Index among Older Adults with Cancer at B.P. Koirala Memorial Cancer Hospital, Chitwan, Nepal

Laxmi Neupane,¹ Hari Prasad Upadhyay,² Nirmal Lamichhane,³

Abstract

Introduction: The number of older adults is increasing day by day. This fact implies important health challenges. Frailty level in older adults having cancer is a globally important health issue. The concept of frailty has become gradually more accepted as one of the most important factors particularly in patients with cancer who are receiving treatment. The objective of the study was to find out the frailty index among older adults with cancer admitted for surgery at BPKMCH, Bharatpur, Nepal. Methods: An analytical cross-sectional study was conducted among 111 older adults. Nonprobability purposive sampling technique was used for data collection. Data were collected by face-to-face interview method using Carolina Frailty Index (CFI) developed from a cancer-specific geriatric assessment. Data was entered and analyzed by using SPSS-20, p-value < 0.05 was considered as statistically significant. **Results:** The age of the respondents ranged from 60 to 87 years with mean + SD: 67.46+6.11. Most common site of cancer was gastrointestinal system (47.7%) and the most prevalent co-morbidities in this study were diabetes mellitus (19.8%) and high blood pressure (18.0%). Based on the CFI score, 82.0% were robust, 11.7% were prefrail and 6.3% were frail. Increasing age (P=0.033) and ethnicity (P=0.042) were associated with frailty. Conclusion: CFI is a practical way to define oncologic frailty. Though it is only a descriptive study, frailty index revealed by this study would provide valuable baseline information for further researchers.

Keywords: Frailty Index, Older Adult, Cancer

Introduction

Older adults are the people who completed the age of 60 years. Worldwide, the number of older adults is increasing day by day. In 2050, 80% of older people will be living lowand middle-income countries. Recently, ageing is an emerging social issue for Nepal.

Life expectancy is continuing to increase. There are 2.2 million people in age 60 and above.⁴ About 60% of cancers occur in people 65 years of age.² Among 6063 diagnosed cancer cases, 2281 (37.8%) were the above 60 years.⁵

The concept of frailty has become gradually more important factor in cancer patients who are receiving treatment with surgery. The multisystem and multidimensional effects of both cancer and surgery highlight the importance of incorporating comprehensive preoperative assessments.⁶ As the individual aged, changes results diminished responsiveness and ability to tolerate cancer treatment.7 Though older adults should be assessed for frailty level to determine the treatment option and surgery is the most effective treatment for early stage of cancers, only 48% consider preoperative frailty assessment is mandatory and 6.4% surgeons use comprehensive geriatric assessment in their daily practice. 8,9,10

In Nepal, frailty was 46.2% and significantly associated with older age (P < 0.001).¹¹ In hospitalized older patients in India, 32% were frail and it was associated with comorbidities, decreased physical and cognitive function, and poor perceptions of health.¹² As median reported prevalence of frailty and Pre-frailty was 42% and 43% respectively, it also recommends routine assessment of frailty.¹³

Among older cancer patients, 58% were categorized as robust, 24% as pre-frail, and 18% as frail. Increasing age ($P \le .001$), lower education ($P \le .001$), and cancer type (P=.002) were associated with increasing levels of frailty.¹⁴ Frailty predict adverse to death. 15 health outcomes assessment can help in choosing the better option for treatment.¹⁶ Comprehensive geriatric assessment and frailty index determination before starting any treatment modality for cancer is mandatory to prevent different complications.¹⁷ There have been few published studies about frailty in

developing world.¹² Yet there is limited knowledge and understanding about frailty.¹⁸ So, this study aims to assess the frailty among older adult with cancer admitted for surgery.

Methodology

A descriptive cross-sectional study was conducted among the older adults admitted for surgery at B.P. Koirala Memorial Cancer Hospital, Chitwan, Nepal. Ethical clearance obtained was from BPKMCH-IRC Bharatpur, Chitwan. Informed written consent was taken from all respondents before data collection. Data was collected by using structured interview schedule through face-to-face interview method and sample was selected by using nonprobability sampling technique. purposive instrument consisted of 2 parts. Part I consists of socio-demographic and health related information. Part II consisted of a structured standard tool "Carolina Frailty Index". It has 8 domains and 36 variables that contain continuous variables with range 0-1(0 =absence of deficit and 1 = presence of Respondent's dignity deficit). maintained by giving them the right to reject or discontinue from the research study at any time if they do not want to participate in the study. Confidentiality was maintained by not disclosing the information to others. All collected data was reviewed and checked daily for its completeness, consistency and accuracy. Data were edited, organized, coded and entered in IBM SPSS Statistics 17 for analysis. Data was analyzed using descriptive and inferential statistics. In the descriptive statistics for categorical variables, frequency and percentage were calculated. While for continuous variables, mean and standard deviation was calculated. In the inferential

statistics to find the association between categorical variable chi-square test was used. P-value <0.05 was considered statistically significant.

Results

(Table 1) Among 111 participants, the age of the respondents ranged from 60 to 87 years with mean \pm SD: 67.46 \pm 6.11. Most common age 65-70 years (35.1%), male (55.0%), underweight or BMI<18.5 (11.7%), Janajati (40.5 %%), Hindu (70.0%) and illiterate were (55.0%). Most of the respondents' occupation was agriculture (65.8%).

(Table 2) showed that, most common site of origin of cancer was gastrointestinal system (47.7%).

(Table 3 and 4) shows the CFI score on different domains and variables. Most prevalent co- morbidities in this study were diabetes mellitus (19.8%) and high blood pressure (18.0%).

(Table 5) showed the CFI score. Based on the CFI score with mean (SD) = .1300 (.11168), majority (82.0%) were robust, 11.7% were pre-frail and 6.3% were frail.

(Table 6) showed the association between CFI scores with different selected variables. Increasing age (P=0.033) and ethnicity (P=0.042) were associated with frailty.

(Table 7) shows the association between frailty index score with site of cancer. This shows that there is no association between frailty index score with site of cancer (p-value>0.05).

Discussion

The concept of frailty and the use of the frailty index has been gradually gaining acceptance for the treatment planning of older adults. It is the first step in assessing the frailty level using Carolina Frailty Index in older adults with cancer admitted for surgery at BPKMCH, Nepal.

This study revealed that, age of the respondents ranged from 60 to 87 years with mean \pm SD: 67.46 ± 6.11 . Nearly similar findings were found in the another study in which among 190 patients, mean age was 70 years (range 65–86). While another

study found that the mean age was 72 years. ²⁰ In this study, most common site of cancer was gastrointestinal system (47.7%) while in another study, among the respondents, the most prevalent form of cancer was colorectal (69.3%).²¹

Most prevalent co- morbidities in this study were diabetes mellitus (19.8%) and high blood pressure (18.0%) while another study showed similar finding on diabetes mellitus (19.0%) and contrast on high blood pressure (50.0%).¹⁴

This study found that, mean (SD) of the CFI was .1300 (.11168) and based on the CFI, 82.0% were robust, 11.7% were pre-frail and 6.3% were frail. Nearly similar finding was found on other study that, 49 (78%) patients were robust, 11 (18%) pre-frail, and 3 (5%) frail. Contrast finding was found on another study which showed that, 58 % were categorized as robust, 24% as pre-frail, and 18% as frail. Similarly other study also found that mean of CFI for the study population was 0.22, with 54% classified as robust, 22% as pre-frail, and 24% as frail. 121

This study showed that increasing age (P=0.033) and ethnicity (P=0.042) were associated with frailty while increasing age $(P\leq.001)$, lower education $(P\leq.001)$, and cancer type (P=.002) were associated with increasing levels of frailty in another study.¹⁴

Conclusion

It is only the descriptive study, finding of this study will provide valuable baseline information for further researcher. The majority of the older adults admitted for surgery were robust. Increasing age and

ethnicity were associated with frailty. So, frailty assessment is more importantly recommended among older adults.
